## ABSTRACT

The present report documents a procedure for the optimum sizing of wing structures that is based on representing the built-up finite element assembly of the structure by equivalent beam models. The reduced-order beam models are computationally less demanding in an optimum design environment which dictates repetitive analysis of several trial designs. The design procedure is implemented in a computer program that requires geometry and loading information to create the wing finite element model and its equivalent beam model, and provides a rapid estimate of the optimum weight obtained from a fully stressed design approach applied to the beam. The synthesis procedure is demonstrated for representative conventional-cantilever and joined wing configurations.

## INTRODUCTION

Automated design synthesis programs provide a significant capability for assessing new concepts in aircraft design. Such concepts invariably entail a multidisciplinary synthesis environment that is characterized by complex analysis codes for various participating disciplines. Since optimum design involves repetitive analysis, the computational costs can be significant, particularly if no effort is made to substitute approximating strategies in lieu of more detailed analyses. The optimum synthesis scenario for the present work resulted from studies directed at the optimum weight evaluation of the joined wing. The joined wing (Ref. 1) is a general concept that seeks aerodynamic and structural advantages by replacing the horizontal tail in a conventional airplane design by a forward swept wing that is joined to the front wing at the tip. The resulting truss-like structure is claimed to have higher stiffness and a significant potential for structural weight savings. References 2 and 3 document the results of studies that primarily examined the sensitivity of key geometric parameters on the optimum weight of the joined wing design. In both of these studies, a finite element analysis capability was employed in conjunction with a nonlinear programming based optimization algorithm to determine the mathematical optima. The computational requirements for these solutions were substantial, thereby precluding other combinations of geometric parameters from consideration. Although these studies were successful in establishing preliminary trends of the optimum weight, the approach of using detailed finite element models with mathematical programming based optimization algorithms was considered inappropriate for a more detailed study. Such a detailed multidisciplinary synthesis study would include optimization for aerodynamics and stability/control in addition to the structural performance.

The purpose of this study was to formulate a procedure for optimum structural design with limitations on computational requirements enforced by a multidisciplinary design environment. The strategy adopted for this task was to replace the built-up finite element model of the wing structure by a lower order beam framework model that would simulate the strength and stiffness characteristics of the former with a minimum loss in accuracy. Subsequent sections of this report describe the approach in greater detail, including its numerical implementation into a synthesis program. An annotated listing of the fortran programs and the related data files can be obtained as an appendix to this report.

## THEORETICAL BACKGROUND

The configuration of an automated synthesis procedure requires careful consideration in the selection of the analysis and optimization capabilities. These programs must incorporate approximating strategies to reduce the overall computational effort and at the same time must retain any peculiar characteristics of the problem. This is particularly true in the case of the joined wing which has rather unique displacement and stiffness characteristics. The present section develops the theoretical concepts that form the basis for the design strategy proposed in this report.

### Joined Wing Structural Analysis

The joined wing configuration results in a stiff load carrying structure which has been shown to yield lower weights than the conventional wing-tail design. The potential for weight reduction is most simply explained by a 'tilted-truss' visualization of the fore-aft wing combination as seen in Figure 1. The front and aft wings form a truss with the primary load carrying plane inclined to the horizontal by an angle which is determined by the dihedral angle of the wings. The aerodynamic loads can be resolved into the inplane and out-of-plane components. The load component perpendicular to the plane of the truss tends to concentrate material on the upper surface of the leading edge and the lower surface on the trailing edge of the wings. The effective beam depth is thus determined by the chord length as opposed to the thickness profile for conventional wings.

The structural joint between the front and aft wings is also critical in determining the optimum weight of a configuration. It is an area of stress concentration and its own rigidity in bending and torsion determines the material distribution on the front and aft wings. Furthermore, the location of the joint along the span also influences the structural weight and the optimal material distribution. The formulation of a mathematical design model should therefore give special consideration to these characteristics.

### Wing Finite Element Modeling

The finite element models for the conventional and joined wing configurations studied in this effort were built-up models with axial rod elements and quadrilateral membrane elements. The plan view and a typical cross section are shown in Figures 2 and 3. Such a single cell representation is considered appropriate in the preliminary design studies for which the model is intended. The consistency of the design and analysis models is also an important consideration in this exercise. At least two chordwise panels are essential in the design model to allow for unsymmetrical distribution of material that is predicted by the tilted bending-axis hypothesis. For an improvement in the stress and displacement results, the analysis model can have any even number of panels in the chordwise direction. The number of spanwise stations is at the discretion of the user and is generally selected to keep the panel aspect ratio close to unity. Ribs, modeled by quadrilateral membrane elements were added to the built-up structure at a specified number of locations.

The joint between the front and aft wings was modeled by a framework of

beam elements as shown in Figure 4. The beam sectional properties were assigned numerical values to generate a structure that was extremely rigid in extension, bending and twisting deformations. The aerodynamic loads are specified as an array of forces at the leading and trailing edges of the structure. A unique feature of this study is the automated generation of the finite element model and will be discussed in a later section.

### Beam Representation of Wing Models

A typical finite element model of a joined wing with a relatively coarse mesh has more than seven hundred degrees of freedom. Repetitive analysis in an optimization exercise with such a large model is prohibitive from a computational standpoint. The approach adopted in the present work replaces the detailed built-up models by equivalent beam models in the design loop.

A cantilever beam has deflection and stiffness characteristics that are very similar to a conventional cantilevered wing. The wing can be regarded as a tapered plate with one end built-in and the other free. The deflection of this plate in its primary bending mode can be represented by a cantilever beam with appropriately matched moment of inertia characteristics. An exact value of the wing moment of inertia cannot be used for the beam as it would result in an artificially stiff structure. This difference is attributed to the phenomenon of shear lag. If one considers the upper and lower surfaces of the wing model as flange elements, shear lag is the description of the state in which the flange strains decrease asymptotically when moving away from the web section. Hence, the bending stiffness computed using the full width of the flange for the moment of inertia would result in a conservative estimate. A reduced flange width should be used and this is dependent on the geometry of the web and flange, wing span, boundary conditions and the bending load distribution. The beam should therefore have a moment of inertia equal to that of the wing multiplied by a reduction factor to account for wide flange effects. In the present exercise, this factor was computed numerically by a process of matching the response of the built-up model to the simplified beam model.

The cross sectional properties of the wing that are represented on the equivalent beam model are the moments of inertia  $I_{xx}$  and  $I_{yy}$ , the product of inertia  $I_{xy}$ , and the torsional constant  $J$  (see Figure 4). The volume of the material per unit length of the wing span is introduced as an additional variable to establish a weight relation between the beam and wing models. The torsional constant  $J$  is computed for a thin-walled closed section by the Bredt formula (Ref. 4)

$$J = \frac{4A^2}{\frac{ds}{t}} \quad (1)$$

The product of inertia term is essential to accomodate the unsymmetrical bending that is present in conventional swept wings and the joined wing configurations. The beam cross section to which these sectional properties are attributed is shown in Figure 5. The five sectional properties described above can be expressed in terms of an equal number of independent wall thicknesses of the cross section. The choice of this cross section was primarily dictated by the anticipated unsymmetrical material distribution in the design of the joined wing. The wall thicknesses, updated during the design process, can result in either a symmetrical or an unsymmetrical cross

section.

The deflections of the equivalent beam structure under the applied loads were computed from a finite element program. The specification of a special beam cross section precluded the computation of element stresses in the same finite element program. These stresses are required for the strength sizing of the beam and were computed in a post-processing program using the following unsymmetrical bending stress relationship (Ref. 5)

$$\sigma_{xx} = - \left( \frac{M_z I_{yy} + M_y I_{yz}}{I_{yy} I_{zz} - I_{yz}^2} \right) y + \left( \frac{M_y I_{zz} + M_z I_{yz}}{I_{yy} I_{zz} - I_{yz}^2} \right) z \quad (2)$$

Here  $M_y$  and  $M_z$  are the bending moments about the  $y$  and  $z$  axes, respectively. The distances  $y$  and  $z$  are measured in a centroidal axes system shown in Figure 6. The bending moments  $M_y$  and  $M_z$  are computed from the moment-curvature relations

$$M_y \approx - EI_y \frac{d^2 w}{dx^2} \quad (3)$$

$$M_z \approx - EI_z \frac{d^2 v}{dx^2} \quad (4)$$

where  $v$  and  $w$  are the deflections in the  $y$  and  $z$  directions, respectively. The curvatures in equations (3) and (4) were obtained from the displacement field by a central finite difference approximation (see Fig. 7)

$$\left. \frac{d^2 w}{dx^2} \right|_i = (w_{i+1} - 2w_i + w_{i-1}) / (\Delta x)^2 \quad (5)$$

$$\left. \frac{d^2 v}{dx^2} \right|_i = (v_{i+1} - 2v_i + v_{i-1}) / (\Delta x)^2 \quad (6)$$

for the station at the root, the boundary conditions at a fixed support can be invoked to obtain the approximation

$$\begin{aligned} w_{-1} &= w_1 \\ v_{-1} &= v_1 \end{aligned} \quad (7)$$

To obtain better approximations for the second order derivatives described above, the step size  $\Delta x$  was reduced by increasing the number of nodes in the beam model. The same effect can also be achieved by using an interpolated

polynomial obtained from the displacement corresponding to a coarser grid model. An approach such as the present one allows the specification of an arbitrary cross section and can be used in conjunction with any finite element displacement analysis program. It can also be used with a displacement field obtained from a classical Galerkin or a Rayleigh Ritz type solution.

### Optimum Structural Design

There are several options available to size the wing and the equivalent beam structures for minimum weight and a prescribed structural strength. The general mathematical problem statement for this problem can be written as

$$\text{Minimize } W(\bar{d}) \quad (8)$$

$$\text{Subject to } g_j(\bar{d}) < 0 \quad j = 1, 2, \dots, m \quad (9)$$

$$\text{and } d_i^L < d_i < d_i^U \quad i = 1, 2, \dots, n \quad (10)$$

Here  $W$  is typically the structural weight;  $\bar{d}$  is a vector of design variables with prescribed lower and upper bounds on its components given as  $d_i^L$  and  $d_i^U$ , respectively. The inequality constraints  $g_j$  can be used to prescribe bounds on strength and nodal displacements. This approach can be integrated into the present design strategy with minor modifications but is computationally demanding in the presence of a large number of design variables and constraints. An alternative strategy referred to as the fully-stressed design approach was implemented instead. This approach is based on the hypothesis that a strength governed design is optimal when all elements are stressed to their maximum permissible limits. The assumption is valid for singly loaded structures that do not have multiple load paths (Ref. 6). The built-up wing finite element model is a redundant structure and cannot be strictly considered as optimum in the fully stressed state. The beam model, however, is considered a good candidate for the fully stressed design philosophy. In previous work it has been shown that the fully stressed design strategy provides a good first estimate of the optimum weight for even mildly redundant structures.

A stress ratio algorithm was implemented in the present work where the  $i$ -th wall thickness at the  $j+1$ -th iteration is given by

$$t_i^{j+1} = t_i^j \frac{|\sigma_i^j|}{\sigma_{all}} \quad (11)$$

The allowable strengths in compression and tension are taken to be equal in the above approach. Bending stresses were recovered from six locations on the cross section and these are labeled one to six in Figure 5. The vertical sections 1-6 and 3-4 were kept equal in the design process. This equality was enforced after each thickness had been obtained independently from equation 11, with the greater value of thickness assigned to the two sections. Each element was sized on the basis of the maximum stress on the element. In the present exercise the stresses are recovered at six locations with each location corresponding to an extremity for an element. More stress recovery

points can be introduced with an insignificant addition in computational time.

Convergence in the stress ratio algorithm is very rapid in the initial stages of the design. When approaching close to the optimum, the design iterations illustrate a 'tail-like' characteristic. Approaches which combine a gradient based search algorithm with such a stress ratio approach have been proposed and will be examined in future work. The other drawback in this approach is the lack of constraints to limit the displacements at nodal locations. This can be circumvented by following up the stress ratio sizing by a redesign based on the energy level in each element with the objective of forcing the element energies to comparable values for all elements in the structure.

#### COMPUTER IMPLEMENTATION

A stated objective of the present work was to generate an automated synthesis procedure for airframe structures suitable for adaptation in a multidisciplinary design environment. In particular, the program was to interact with aerodynamic design codes that were in turn driven by external optimization programs. Thus, the generation of the wing finite element model, its reduction to an equivalent beam model and the subsequent optimum design of the beam had to be completely automated. Engineering Analysis Language (EAL, see Ref. 7) was used for all structural analysis in the present task. The fortran programs that automatically generate runstreams for various segments of the program are currently written for EAL. However, these programs can be adapted for other finite element environments with minor modifications. The organization and execution of these program is controlled in the Command Language feature on DEC systems. A flowchart depicting the order of execution is shown in Figure 8. The primary function of each module is discussed next and the corresponding input/output requirements are detailed in the appendix.

#### COORDS:

This program provides an automated finite element modeling capability for conventional and joined wings. The user provides input information pertaining to the type of structure, semi-span, root and tip chords, thickness ratio, 1/4-chord sweep and the dihedral angle. Additional information is also provided on the number of chordwise and spanwise stations, sizes of elements, and the number of ribs in the model. The program then generates a finite element model of the structural box using axial rod elements for stringers and quadrilateral membrane elements for the plate sections. This model includes complete description of nodal co-ordinates, element connectivity and distribution of nodal loads. In its present form, this information is available as an EAL input runstream. Suitable modifications of format statements can adapt this program for other finite element codes. The program additionally generates data files that provide input data for programs executed later in the optimization sequence. In particular, these files transfer information related to wing geometry, loads, cross sectional geometry and element sizes.

#### MOMNT:

The cross sectional properties of the wing finite element model are

computed in this program. At each of the span stations specified by the user, the sectional moments and products of inertia, torsional constant and mass per unit span are computed and data files generated to transfer this information to a program which generates an equivalent beam model with the same sectional properties.

#### BEAM:

For the built-up finite element model of the wing created in program COORDS, this program creates an equivalent finite element model with beam elements located at the wing elastic axis. For a conventional wing, the equivalent model is a cantilevered beam with section properties equal to those obtained from MOMNT. The number of beam elements used in modeling this equivalent beam is identical to the number of spanwise stations entered in COORDS. The modeling is similar for the joined wing configuration with the exception that there is an equivalent beam for each of the front and aft wings and the joint between the beams is simply modeled as a common node. The two equivalent beams are built-in at the root and permit the joint to be located arbitrarily along the span. Element connectivity, load specifications and other execution runstream are in context of EAL but can be modified for other finite element programs.

#### SHLAG:

This program is used to provide the correction required in the wing sectional properties before they are transferred to the beam model. The moment of inertia about the primary bending axis of the wing would result in a stiffer beam because of shear lag effects. This program reads the maximum displacements, W, of the wing and beam models and defines a constant ' $\rho$ ' where

$$\rho = \frac{(W_{\max})_{\text{beam}}}{(W_{\max})_{\text{wing}}} \propto \frac{(EI)_{\text{wing}}}{(EI)_{\text{beam}}}$$

The chord on the beam and wing structural box were kept the same and the height of the beam section was changed to account for the shear lag effects. If the moment of inertia corresponding to the thin sidewalls in the beam is neglected, the bending rigidity is proportional to the square of the depth, d

$$(EI) \propto d^2$$

$$d_{\text{wing}} = \sqrt{\rho} d_{\text{beam}}$$

Numerical evaluation with test cases shows this to be a reasonable assumption. The effect of wing sweep and dihedral was also incorporated in this program.

#### BSAP:

The section properties of a general beam section with five independent wall thicknesses as shown in Figure 5 are computed in this program. All section properties are computed about a centroidal axis which is also computed

in this segment. Since the finite element program EAL needs section properties about the principal axes system for a section, additional computations are necessary to transform centroidal properties to principal axes properties. The orientation of the principal axes system with respect to the global axes system is necessary to complete element coordinate axes definitions and was therefore computed in this program. In addition, the location of the six stress recovery points in terms of y-z coordinates change with each iteration and were computed here.

#### MODISP:

This program is identical to BEAM except that it is configured to double the number of elements from the previous beam finite element model. This was necessary to increase the number of nodal points at which the displacements were computed so as to enhance the quality of the finite difference approximations for curvature. The section properties for each element were transferred from the BSAP program and used here to create an EAL runstream for the equivalent beam.

#### STRESS:

The bending stresses necessary in the resizing algorithm were computed in this program. The beam displacements are read in from a data file and used to compute the curvatures and hence also the components of the sectional bending moment. At the stress recovery points obtained in BSAP, the stresses were computed using equation 2. These stresses were placed in an output file to be accessed by the design optimization program.

#### FSD:

This is the computer implementation of the fully stressed design strategy discussed in an earlier section. The wall thicknesses of each element are transferred to this program as are the stresses computed in program STRESS. The stress ratio algorithm (Eq. 11) is used to resize the wall thicknesses based upon the most recently computed stresses and a user specified allowable stress. The weight computed in three consecutive passes of the sizing algorithm is used to terminate the optimization iterations based upon a user specified value for the relative change in the weight.

In the sizing algorithm there are two items of which a user should be aware. The vertical walls of the beam section are kept equal and the largest stress of the four corners of the section is used to determine this thickness. Additionally, lower and upper bounds are imposed on the thickness of the walls and these stem from two considerations. The wall thicknesses must be kept such that they are physically meaningful dimensions within constraints imposed by fixed width and depth of the section. Furthermore, the wall thicknesses should not be so large as to create a conflict with the thin wall assumptions used in computing the beam sectional properties.

## NUMERICAL RESULTS

The structural resizing procedure described in the preceding sections was validated through a sequence of test problems consisting of both the joined and the conventional wing configurations. The primary objective of the present study was to establish trends on the deflection characteristics and

the optimum structural weight as predicted by the equivalent beam models, and to compare these trends with those obtained from a fully stressed design of a built-up finite element model of the wing. The geometry parameters considered in this validation study include the wing sweep and dihedral angle, and the spanwise location of the joint between the front and aft wings for the joined wing configuration. The numerical results for the various test cases are summarized in Tables 1 - 4. The shear lag effects described in an earlier section are also dependent upon the geometry of the configuration. The variation of these influences with sweep and dihedral were established by a series of numerical experiments and the trends were mapped into cubic spline functions for the purpose of interpretation for intermediate values. These spline functions are valid for sweep angle variations between 10° and 30° and dihedral angle variations between 4° and 20°.

Table 1 lists the optimum structural weights for a conventional cantilever wing with a dihedral angle of 4° and various sweep angles. The wing span and the root and tip chords were held to constant values as the sweep angle was varied. An increase in structural weight is expected with increasing sweep angle and is clearly indicated by both the wing and the equivalent beam models. The material distribution on the beam was similar to a conventional wing with maximum material located at the root section. Results for a similar parametric variation of the sweep angle for similar loading of a joined wing configuration are shown in Table 2. The front and aft wings were identical and have a dihedral of  $\pm 4^\circ$ , respectively. The optimum weight of the beam model displays the same qualitative trend as the built-up finite element model. Furthermore, the deflection characteristics of the two models also display the same behavior, with the maximum displacement occurring at about 70% of the semi-span. Consequently, the material distribution along the span also displays similar qualitative trends.

The influence of the dihedral angle on the optimum weight is illustrated in Table 3. With increasing dihedral angle, the tilted-truss effect of the joined wing structure becomes more predominant. The effective depth of the beam is increased and provides for a reduction in the structural weight. The effect of material concentration at the upper leading edge and the lower trailing edge of the wing structural box was present in the built-up finite element model and was clearly evident in the equivalent unsymmetrical beam cross section obtained from a fully-stressed design of the beam model. The results presented are for a  $\pm 25^\circ$  sweep of the quarter chord lines of the front and aft wings.

Table 4 demonstrates the influence of moving the joint between the front and the aft wings inboard from the tip. A decrease in structural weight is demonstrated in both the built-up wing models and the equivalent beam representations. These results are for a dihedral of  $\pm 4^\circ$  and a quarter chord sweep of  $\pm 25^\circ$ , respectively.

#### CONCLUSIONS AND RECOMMENDATIONS

This report describes a procedure for optimum structural design in a preliminary design environment where computational efficiency is a primary consideration. Rapid estimates of the optimum structural weight of wing structures for a specified load are obtained by the automated synthesis of representative beam models which have considerably fewer degrees of freedom. The underlying design criterion for minimum weight is to stress each element

to its ultimate load carrying capacity. The most significant advantages of the proposed procedure are

- a) automation of the design process to make the synthesis procedure easily adaptable in a multidisciplinary design environment. This includes an automated creation of all finite element models required in the process
- b) considerable savings in computational resources over the conventional approach of optimizing detailed built-up models of the wing structure.

Although the automated process provides a reasonable strategy for preliminary design, additional effort is required to enhance its effectiveness as a robust design tool. These modifications can be summarized as follows

- a) Prescribing bounds on nodal displacements in addition to constraints on strength. In the present approach, this can be obtained by creating a sizing ratio based on the strain energy within the element
- b) The potential of the present approach can be extended further by adding the ability to recover element sizes of the built-up finite element of the wing from the optimized sections of the beam. In the present model, the five independent membrane element thicknesses can be related to the five optimized values of the sectional properties through nonlinear relations. Reasonable qualitative estimates of these dimensions can be obtained from the optimized beam and used as input to a nonlinear equation solver to recover more precise values.

## ACKNOWLEDGEMENTS

The author gratefully acknowledges the contributions of graduate student J. L. Chen during the course of this study. The author would also like to thank Mr. W. H. Reuter and J. R. Dennison for their assistance in the programming effort involved in the project.

## APPENDIX

This appendix documents the input/output file specifications and an annotated listing of all fortran programs and pertinent data files used in the optimum synthesis procedure. The function of each of these programs is described in the report. Table A-1 summarizes the data files used for input/output functions in each of the major program segments.

The annotated listings are self explanatory and can be used as a guide if program modifications are attempted. Numerical constants that are hardwired into the programs and cannot be altered by input data specifications are identified in these listings.

16. Abstract  The present report documents a procedure for the optimum sizing of wing structures that is based on representing the built-up finite element assembly of the structure by equivalent beam models. The reduced-order beam models are computationally less demanding in an optimum design environment which dictates repetitive analysis of several trial designs. The design procedure is implemented in a computer program that requires geometry and loading information to create the wing finite element model and its equivalent beam model, and provides a rapid estimate of the optimum weight obtained from a fully stressed design approach applied to the beam. The synthesis procedure is demonstrated for representative conventional-cantilever and joined wing configurations.
